Transfer of Learned Opponent Models in Zero Sum Games

12 Introduction

11

Being able to transfer previously acquired knowledge to a new domain is one of the 13 hallmarks of human intelligence. Humans are naturally endowed with the ability to extract 14 relevant features from a situation, identify the presence of these features in a novel setting 15 and use previously acquired knowledge to adapt to previously unseen challenges using 16 acquired knowledge. More formally, Perkins (1992) defines transfer of learning as the 17 application of skills, knowledge, and/or attitudes that were learned in one situation to 18 another learning situation. This typically human skill has so far eluded modern AI agents. 19 Deep neural networks for instance can do very well on image recognition tasks and can even reach super-human performance levels on video and strategic board games. Yet they struggle 21 to learn as fast or as efficiently as humans do, and more importantly they have a very limited ability to generalize and transfer knowledge to new domains. Lake, Ullman, Tenenbaum, & Gershman (2017) argue that human learning transfer abilities take advantage of important cognitive building blocks such as an abstract representation of concepts underlying tasks and compositionally structured causal models of the environment.

One way to build abstract representations of the environment when the task involves interactions with others is to build a model of the person we are interacting with that may inform what actions they are likely to take next. Once we learn something about them, we can use this knowledge to inform how to best behave in novel situations. This may lead to very efficient generalization of knowledge, even to situations that are dissimilar to the history of interaction, assuming what we have learned about others is an abstract representation that is not too dependent on the environment of the initial interaction. There is evidence that people learn models of their opponents when they play repeated economic games (Stahl & Wilson, 1995), engage in bilateral negotiations (Baarslag, Hendrikx, Hindriks, & Jonker, 2016), or simply try to exploit a non random player in chance games such as

Rock-Paper-Scissors (Weerd, Verbrugge, & Verheij, 2012). In this paper, we are specifically interested in the way in which people build and use models of their opponent to facilitate learning transfer, when engaged in situations involving an interaction with strategic considerations. These situations arise frequently such as in negotiations, auctions, strategic planning and all other domains in which theory of mind abilities (Woodruff, Sciences, Brain, & 1978, n.d.) play a role in determining human behaviour. In order to explore learning transfer in these strategic settings, it is generally useful to study simple games as a model of more complex interactions. More specifically, we need a framework that allows the study of whether and how a player takes into consideration, over time, the impact of its current and future actions on the future actions of the opponent and the future cumulative rewards.

Repeated games, in which players interact repeatedly with the same opponent and have the ability to learn about the opponent's strategies and preferences (Mertens, 1990) are particularly adapted to the task of opponent modelling.

Early literature on learning transfer in games has mostly focused on measuring the 50 proportion of people who play normatively optimal (Nash Equilibria) or salient actions (e.g. 51 Risk Dominance) in later games, having had experience with a similar game environment previously. For instance, Ho. Camerer, & Weigelt (1998) measure transfer as the proportion of players who choose the Nash Equilibrium in later p-beauty contest games, after training on similar games. They find there is no evidence of immediate transfer (Nash equilibrium play in the first round of the new game) but positive structural learning transfer as shown by 56 the faster convergence to equilibrium play by experienced vs non experienced players. Knez & Camerer (2000) test learning transfer in players exposed to two games with multiple equilibria sequentially and explore the ability of players to coordinate their actions to choose a particular equilibrium in subsequent games having reached it in prior ones. They distinguish between games that are similar in a purely descriptive way, meaning similar choice labels, identity of players, format and number of action choices; and games that are similar in a strategic sense, meaning similar payoffs from combination of actions, identical

equilibrium properties or significant social characteristics of payoffs such as possibility of punishment, need for fairness and cooperative vs competitive settings. They find that transfer of learning (successful coordination) occurs more readily in the presence of both descriptive and strategic similarity. If the games were only strategically similar, then the transfer was much weaker.

Juvina, Saleem, Martin, Gonzalez, & Lebiere (2013) made a similar distinction between 69 what they deemed surface and deep similarities and find that both contribute to positive 70 learning transfer. However, they show that surface similarity is not necessary for deep 71 transfer and can either aid or block this type of transfer depending on whether it leads to congruent or incongruent actions in later games. In a series of experiments using economic signalling games (Cooper & Kagel, 2003, 2008) the researchers found that participants who have learned to play according to Nash Equilibrium in one game can transfer this to subsequent games, even though the actions consistent with Nash Equilibrium in later games 76 are different. They show that this transfer is driven by the emergence of sophisticated players who are able to represent the strategic implications of their actions and reason about 78 the consequences of changed opponent payoffs. 79

Most of these studies fail to offer a formal explanation of this transfer or a modelling
framework that can explain the experimental observation of transfer between games and
generalise it to extensive classes of games. A notable exception is the effort by Haruvy &
Stahl (2012) to specify a model of learning where players learn abstract rules that they can
generalise and transfer across dissimilar games, rather than action choices that can only be
used within the same game. Participants played ten games, presented as 4x4 normal form
(matrix payoffs). Their results suggest that subjects do transfer learning over descriptively
similar but strategically dissimilar games and that this learning transfer is significant. They
also showed that players learn abstract aspects of the game that are then transferred to new
settings. Their rule-learning model, based on Stahl & Wilson (1995), was able to capture

participants' dynamic behavior and show that the propensity to select particular rules is perfectly transferred across games.

Still, one of the commonalities in studies of how humans adapt to computerised 92 opponents is that they have mostly looked at the ability of players to detect and exploit action-based learning rules. The strategies implemented by the computer opponents had a style of play that was not "human-like" in the sense that humans are not very good at playing specific mixed strategies with any precision of at detecting patterns from long sequences of past play due to cognitive constraints. It is therefore important to have agents that "play like humans", and one way of achieving that is to embed theses agents with human-like theory of mind abilities based on limited steps of recursive reasoning. Simon (1972) explains that humans have limited cognitive capacities and as such cannot be expected 100 to solve computationally intractable problems such as finding Nash equilibria. Instead, they 101 will try to "satisfice" by choosing a strategy that is adequate in a simplified model of the 102 environment, rather than an optimal one. This concept finds its natural application in 103 "level-k" theory, first adopted by Stahl & Wilson (1995). It posits that deviations from Nash 104 equilibrium solutions in simple games are explained by the fact that humans have a 105 heterogenous degree of strategic sophistication. At the bottom of the ladder, level-0 players 106 are non-strategic and play either randomly or use a salient strategy in the game environment 107 Arad & Rubinstein (2012). Level-1 players are next up the ladder of strategic sophistication 108 and will assume all their opponents belong to the level-0 category and as such will best 109 respond to them given this assumption. Likewise, a level-2 player will choose actions that are 110 the best response given the belief that all opponents are exactly one level below, and so on. 111

In this study, we propose to explore opponent modelling and its transfer with the use of computer agents possessing human-like theory of mind abilities with limited degrees of iterated reasoning. The agents will have a fixed strategy played stochastically and will either be level-1 or level-2 behavioral rule, mimicking human theory of mind abilities and the

limited recursion depth they exhibit Goodie, Doshi, & Young (2012).

Our choice of using computer oponents instead of matching groups of participants 117 makes it easier to disentangle the process of learning about the opponent from that of 118 learning about the game structure and payoffs. When playing against other human 119 opponents, players are learning about the game and the strategy of the opponent simultaneously. Thus, it is harder to focus on an individual and how her strategies are 121 changing and adapting to the opponent's play if we cannot experimentally control the 122 behaviour of the opponent. The use of computer opponents to elicit learning behavior has 123 been explored in the literature with encouraging results. For instance, Spiliopoulos (2013) made humans play constant sum games against 3 computer opponents programmed to take advantage of known patterns in human play such as imperfect randomization and heuristics 126 use and found that human participants do adapt to the opponent they are facing. Shachat & 127 Swarthout (2004) made human participants face computer opponents playing various mixed 128 strategies in a zero-sum asymmetric matching pennies game. They found that the players 129 changed their strategies towards exploiting the deviations from the Mixed Strategy Nash 130 Equilibrium (MSNE), and that this exploitation was very likely if the deviation from the 131 MSNE play was high.

We chose to use a set of purely competitive zero-sum games that incentivise reasoning
about the opponent without introducing social confounding factors. We avoid social dilemma
and coordination games that crystallise the conflict between competing with others out of
self-interest or cooperating to reach a socially optimal outcome. Playing these games
repeatedly implicates important social constructs such as reputation building, trust and
other individual psychological attributes such as cooperativeness and inequity aversion.
Coordination games also test the ability of choosing the safe self-interested choice compared
to the risky cooperative choice and may depend on similar latent factors. As such, these
confounding factors may impede teasing out the process of learning an opponent model and

that of whether/how these models are transferred. By contrast, purely competitive settings 142 and zero sum games in particular would be more appropriate. They do not incentivize any 143 cooperation, since one player's gain is necessarily the opponent's loss, and are agnostic to 144 trust mechanisms or reputation building. Also choosing games with no pure strategy Nash 145 Equilibrium shift the focus away from learning a normatively optimal action to that of 146 reasoning dynamically about the opponent which is more amenable to modelling learning. 147 Games with unique mixed strategy Nash equilibrium leading to nil average rewards facilitate 148 inferring whether participants have learned to exploit the non-random play of the opponent. 149

We measure transfer of learning about the opponent strategy between games with
varying degrees of similarity. The first two games we use are identical except for action
labels. In one experiment, the third game is strategically similar to the first two but
descriptively different, while in a second experiment, we introduce a third game that is
dissimilar to the first two in terms of payoff matrix and strategic structure while retaining,
like all other games, a unique mixed strategy Nash equilibrium of random action with a fixed
expected reward against a Nash player.

Hence, we ran a total of two experiments where human participants played 3 different games against either 1 (first experiment) or 2 (second experiment) computer opponents. In the following sections, we will describe each experiment's methodology and results separately, then discuss the findings before using computational modelling to shed light on some of the results.

Experiment 1

163 Methods

162

164 Participants

A total of 52 (28 female, 24 male) participants were recruited on the Prolific Academic platform. The mean age of participants was 31.2 years. Participants were paid a fixed fee of £2.5 plus a bonus dependent on their performance which averaged £1.06. The study used a 2 (computer opponent levels 1 and 2) by 3 (games of rock-paper-scissors, fire-water-grass and numbers) design, with repeated measures on the second factor.

70 Procedure

In the first experiment, participants played 3 games sequentially against the same 171 computer opponent. The computer opponent either used a level-1 or level-2 strategy. The 172 three games were rock-paper-scissors, fire-water-grass and the numbers game. A typical 173 rock-paper-scissors game (hereafter RPS) is a 3x3 zero sum game, with a cyclical hierarchy 174 between possible actions: rock blunts scissors, paper wraps rock, and scissors cut paper. If 175 one player choses an action which dominates their opponent's action, the player wins 176 (receives a reward of 1) and the other player loses (receives a reward of -1). Otherwise it is a 177 draw and both players receive a reward of 0. It has a unique MSNE consisting of randomly playing one of the three options each time. 179

The second game is identical to Rock-Paper-Scissors in all but action labels. We call it
Fire-Water-Grass (FWG): Fire burns grass, water extinguishes fire, and grass absorbs water.
We are interested in exploring whether learning is transferred in a fundamentally similar
game where the only difference is in the description of the choice actions. Finally, the
numbers game is a generalization of rock-paper-scissors. In the variant we use, 2 participants
concurrently pick a number between 1 and 5. To win in this game, a participant needs to
pick a number exactly 1 higher than the number chosen by the opponent. For example, if a

participant thinks their opponent will pick 3, they ought to choose 4 to win the round. To 187 make the strategies cyclical as in RPS, the game stipulates that the lowest number (1) beats 188 the highest number (5), so if the participant thinks the opponent will play 5, then the 189 winning choice is to pick 1. This game has a structure similar to RPS in which every action 190 is dominated by exactly one choice. All other possible combination of choices that are not 191 consecutive are considered ties. A win would add 1 point to the score of the player, while a 192 loss deduces one point and a tie does not affect the score. Similar to RPS, the MSNE is to 193 play each action with equal probability in a random way. 194

Participants were informed they would play three different games against the same 195 computer opponent. Each participant plays all three games consecutively and in the same 196 order described above. Participants were told that the opponent cannot cheat and will choose its actions simultaneously without knowledge of the participant's choice. A total of 50 198 rounds of each game was played with the player's score displayed at the end of each game. 199 The score was calculated as the number of wins minus the number of losses. Ties did not affect the score. In order to incentivise the participants to maximise the number of wins against the opponents, players were paid a bonus at the end of the experiment that was 202 proportional to their final score. The overall score of the players was translated into the 203 bonus by making each point worth £0.02. This bonus is significant as players could increase 204 the total payoff from the experiment by up to 60% assuming they'd won all rounds against 205 the computer opponent. An example of the interface for the rock-paper-scissors game is 206 provided in Figure 1. 207

208 Results

Looking at the aggregate scores (See Figure 2), the RPS game had the lowest average score across participants (M = 0.289, SD = 0.348) followed by NUMBERS (M = 0.31, SD = 0.347) and finally the FWG game had the highest average score (M = 0.454, SD = 0.354).

Aggregate average scores for each game were significantly different from 0 (hypothesised

Figure 1. Screenshot of the feedback at the end of a round of Rock-Paper-Scissors

value of random play) using parametric one sample t-tests (RPS: t(51) = 7.26, p-value < 0.001; FWG: t(51) = 10.04, p-value < 0.001; NUMBERS: t(51) = 7.17, p-value < 0.001).

To analyse within and between game learning, we used a 2 (condition: level-1, level-2) 215 by 3 (game: RPS, FWG, NUMBERS) by 2 (block: first half, second half) repeated measures 216 ANOVA with the first factor varying between participants. There was a main effect of Game 217 $(F(2,100) = 8.54, \eta^2 = 0.05, p < 0.001)$, showing that average scores varied significantly over 218 the games. Post-hoc pairwise comparisons showed that performance in the FWG game was 219 significantly higher than in the RPS game (t(100) = 3.78, p = 0.0008), and the performance in NUMBERS was significantly lower than FWG game (t(100) = -3.32, p = 0.0024). The score in RPS was not significantly different from the score in NUMBERS however (t(100) = 0.45, p = 0.65). The main effect of Block (F(1,50) = 22.51, p < .001, $\eta^2 = 0.03$) shows 223 that the average score in the first half of games (M = 0.29) was significantly lower than in 224 the second half of the games played (M = 0.40), which translates to within-game learning. 225

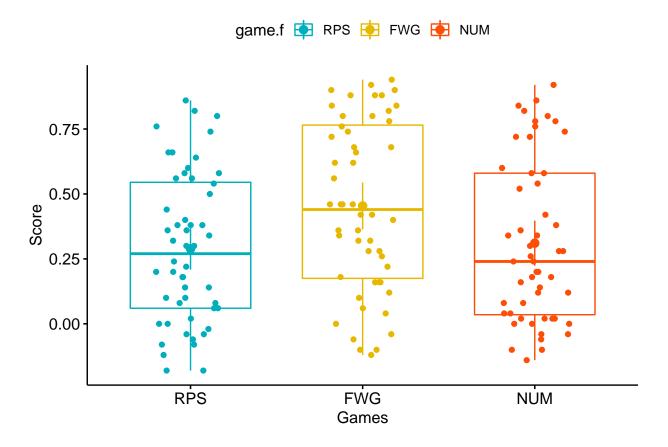

Figure 2. Average scores per game across conditions

As players interact more with the agent, they learn how to win more often. The main effect of Condition $(F(1,50) = 5.44, p = .024, \eta^2 = 0.05)$ indicates that scores were higher against the level-1 player (M = 0.43) than against the level-2 player (M = 0.27). This means that it was harder for participants, on average, to learn the strategy of the more sophisticated opponent (level-2) compared to that of the comparatively less sophisticated agent (level-1).

Finally, the analysis showed a significant interaction effects of block by game (F(2,100) = 6.92, p = .002, $\eta^2 = 0.02$), indicating that within-game learning differed between the games. Indeed, second half scores in RPS are significantly higher than first-half scores (t(150) = 5.59, p < .0001), while there was no significant difference between block scores for the other two games. This is indicative of the significant within game transfer within the first game when players have no epxerience against the opponent, as opposed to much lower

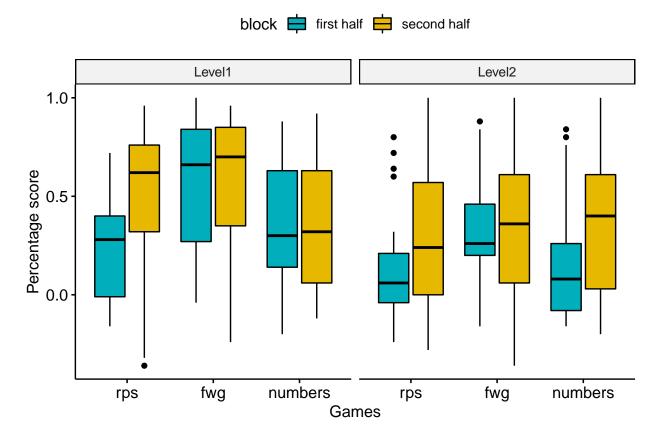

Figure 3. Average scores by game, block and condition

within game performance improvement in the latter games when participants have had some 237 exprience playing against the opponent and start with higher scores indicative of transfer. 238 There was also a three-way interaction between condition, game, and block (F(2,100) = 3.88239 , p = .023, η^2 = 0.01), which indicates, as seen in Figure 3 that within-game learning 240 changes across games also depend on the sophistication of the opponent. For instance, there 241 is more within game learning in the third game against level-2 opponents, since the initial 242 scores are lower than agaisnt level-1 opponent. The explanation for this will become clearer 243 when we discuss the factors moderating learning transfer in the next section. 244

Learning transfer. As a measure for learning transfer, we focus on participants'
scores in rounds 2-6, excluding the very first round for which the agent is programmed to
play randomly as it has no data on prior rounds on which to build its response. A group of

players with no experience of the game are expected to have scores not significantly different from 0. Any significantly positive group average scores would therefore reflect prior learning from past experiences.

We test the average scores for each game against a hypothesised value of 0 for a non-experienced player using parametric one sample t-tests. As expected for the initial RPS game, the average score is not significantly different from 0 as this is the first game and no learning is possible (t(148.85) = 1.04, p = 0.89). In FWG, the score is significantly higher than 0 (t(148.85) = 4.58, p < 0.0001). This is also the case for the more dissimilar game: NUMBERS (t(148.85) = 3.00, p = 0.0092).

Next, we explore whether learning transfer is moderated by the type of opponent and game similarity. Figure @ref(fig: exp1-score-by-opp) shows the mean scores for rounds 2-6 by game for both level-1 and level-2 facing players. Graphically we can see that the pattern is dissimilar between level-1 and level-2 players, and we suspect transfer to be positively associated with similarity and negatively with degree of sophistication of the agent. To test these hypotheses, we run statistical tests on early round scores by game and opponent against the null hypothesis of 0 (no transfer).

For level-1 facing players, there is evidence of learning transfer from RPS to both FWG (t(150) = 3.96, p < 0.001) and NUMBERS (t(150) = 3.74, p < 0.001). For level-2 facing players, there is evidence for transfer from RPS to the similar game FWG, albeit scores are lower than for level-1 player (t(150) = 2.48, p = 0.01) but not to the dissimilar game of NUMBERS.

Our results when averaging across conditions (previous section) showed that there was indeed evidence for transfer to the more dissimilar game (NUMBERS). We can see from splitting the participants by opponent faced that this transfer is exclusively driven by level-1 facing players, as average early round scores of level-2 facing players are close to nil in the

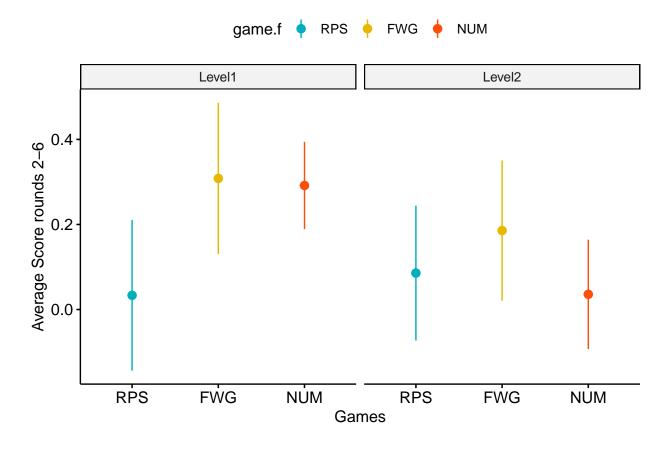

Figure 4. Average early scores by game and type of opponent faced

NUMBERS game. Therefore, both participants facing level-1 and level-2 agents can transfer learning to the similar game, but only those facing the less sophisticated opponent are able to generalise to the less similar game.

Second Experiment

277 Methods

276

Participants. A total of 48 participants (21 females, 28 males, 1 unknown) used the
Prolific Academic platform to participate in the experiment. This was a new set of
participants unrelated to those taking part in Experiment 1. The average age of players was
30.2 years, and the mean duration to complete the task was 39 minutes. Participants were
incentivised using a two-tier payment mechanism: a fixed fee of £2.5 for completing the
experiment plus a performance linked bonus that averaged £1.32.

The participants each played 3 games sequentially against both level-1 284 and level-2 computer opponents, rather than just one like in the first experiment. The three 285 games were Rock-Paper-Scissors, Fire-Water-Grass, and the penalty shootout game. The 286 first two games were identical to the ones used in the first experiment. In the final game (shootout) the participants played the role of the player shooting a football (soccer) penalty, and the AI opponent was the goalkeeper. Players had the choice between three actions, like 289 in the first two games: Shooting the football to the left, right or centre of the goal. If the 290 player shoots in a direction different from that of where the goalkeeper dives, they win the 291 round and the goalkeeper loses. Otherwise, the goalkeeper catches the ball and the player 292 loses the round. There is no possibility of ties in this game. Figure XXXXXXXXX shows a 293 snapshot of play in the shootout game. What makes this game different however is that 294 there are two ways to beat the opponent in each round: if we think the opponent is going to 295 choose "'right" in the next round, we can win by both choosing "'left" and "'center". A 296 level-1 player (thinks that his opponent will repeat his last action) has two ways to win the 297 next round. As such, we have programmed the level-2 computer program to choose randomly 298 between the two possibilities that a level-1 player may choose. 299

Like in the first experiment, the computer opponents retained the same strategy
throughout the 3 games, however the participants faced each opponent twice in each game.

Specifically, each game was divided into 4 stages numbered 1 to 4, consisting of 20, 20, 10, and 10 rounds respectively for a total of 60 rounds per game. Participants start by facing one of the opponents in stage one, then face the other in stage two. This is repeated in the same order in stages 3 and 4. Which opponent they faced first was counterbalanced. All participants engage in the same three games (namely RPS, FWG and Shootout) in this exact order, and were aware that the opponent was not able to know their choices beforehand but was choosing simultaneously with the player.

In order to encourage participants to think about their next choice, a countdown timer of 3 seconds was introduced at the beginning of each round. During those 3 seconds, 310 participants could not choose an option and had to wait for the timer to run out. A small 311 delay that changed randomly (between 0.5 and 3 seconds) was also introduced in the time it 312 took the AI agent to give back their response to make it seem like it is also thinking about 313 its last actions, as a way of simulating a real human opponent. After each round, the 314 participants were given detailed feedback about their opponent actions as well as whether 315 they won or lost the last round. Further information about the outcome of previous rounds 316 was also visible on the game screen below the feedback area, throughout each stage game 317 and opponent could go back many rounds to study the history of interaction. The number of 318 wins, losses and ties were clearly shown at the top of the screen for each game, and this 319 scoreboard was reinitialised to zero at the onset of a new stage game. 320

Like games used in the first experiment, all the games used in this seeting have a unique MSNE consisting of randomising across actions. If participants follow this strategy, or simply don't engage in learning how the opponent plays, they would score 0 on average against both level-1 and level-2 players. Evidence of sustained wins would indicate that participants have learned to exploit patterns in the opponent play.

Results

The RPS game had the lowest average score per round (M = 0.194, SD = 0.345) 327 followed by FWG (M = 0.27, SD = 0.394) and finally the Shootout game had the highest 328 average score (M = 0.622, SD = 0.326). The higher score in shootout is expected as there 329 are 2 out of three possible winning actions, compared to one out of three in RPS and FWG. 330 Indeed, a player not aiming to uncover the opponent's strategy and thus choosing to play 331 randomly should be expected to have on average score per round of 0 in both RPS and 332 FWG, and 0.33 in the Shootout game. To make the scores more comparable, and because we 333 are interested in player's performance that is not due to chance, we will adjust all scores in 334 the shootout game by subtracting the average score per round of a random strategy (0.33). 335 Using parametric t-tests on adjusted scores, we reject the null hypothesis of random play in 336 all three games (RPS: t(49) = 6.26, p-value < 0.0001; FWG: t(49) = 7.25, p-value < 0.0001; Shootout: t(49) = 13.61, p-value < 0.0001).

Using the average scores obtained by participants in each game and interaction, we explore whether learning has occurred within and between games. We perform a two (condition: level-1 first, level-2 first) by two (opponne type: level-1 or level-2) by three (game: RPS, FWG, Shootout) by two (interaction: first or second) repeated measures ANOVA with the first factor varying between participants.

There is evidence for a main effect of Game on scores (F(1.85,88.7) = 11.81, $\eta^2 = 0.04$, p < .0001). To explore these differences further, we look at post-hoc analyses for pairwise comparisons between game scores (p-values adjusted using Holm method for multiple comparisons). We find the performance in the games increases steadily throughout the experiment, with FWG performance significantly higher than RPS (t(96) =2.53, p = 0.025), and performance in the Shootout game also significantly higher than in FWG (t(96) = 2.32, p = 0.025). There was no main effect of either opponent type, the interaction factor (first or second time opponent was faced), or the condition factor (whether level-1 or level-2

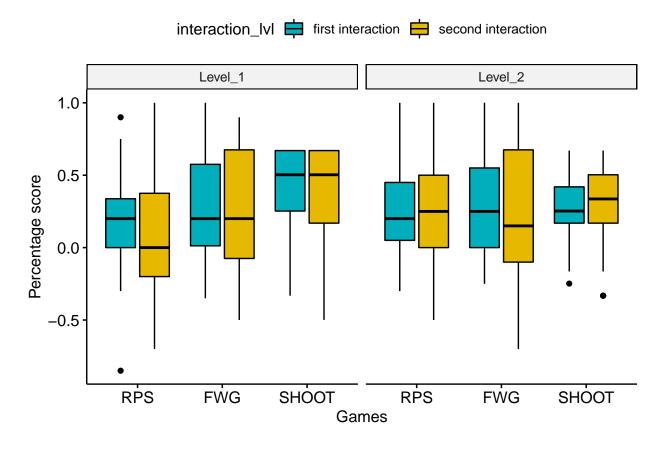

Figure 5. Average scores per game by opponent type

opponent was faced first). This means that neither the type of opponent faced, nor whether 352 it was the first or second interaction with the opponent nor which opponent was faced first 353 did have a main effect on performance. There was however a significant interaction effect 354 between Game and opponent type ($F(1.7, 81.82) = 5.31, \eta^2 = 0.02, p = .01$). As can be seen 355 in Figure 5, when facing level-1 agents, scores increase steadily after each game, with FWG 356 score sgnificantly higher than RPS (t(191) = 2.70, p = 0.03) and Shootout scores in turn 357 significantly higher than FWG (t(191) = 3.05, p = 0.01). There was no significant difference 358 between average scores on any two games when facing level-2 agents however. 359

Learning transfer. As a measure for learning transfer we will again compare scores only on rounds 2-6 of each game, excluding the very first round where play is necessarily random. Because the number of rounds here is very limited, there should be very little

learning within games, and we should be better measure learning transfer if it exits.

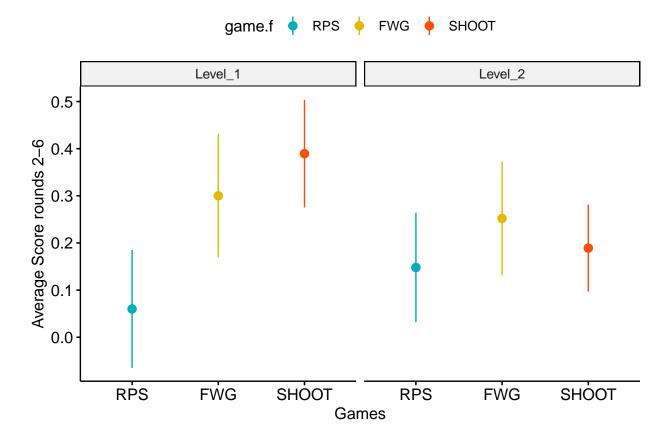

Figure 6. Average early round scores by game for experiment 2

In Figure 6, we show the average score across participants in rounds 2-6 of the first 364 interaction with the opponent for each game. These scores are also averaged across the levels 365 of condition (meaning they are irrespective of which opponent players faced first). For both 366 the FWG and Shootout games, score in the early rounds of the first interaction are 367 significantly higher than 0 for both opponent types. (Level-1 opponent: FWG: t(270) = 4.99, p < 0.0001; Shootout: t(270) = 6.66, p < 0.0001; Level-2 opponent: FWG: t(270) = 4.40, p < 0.0001; Shootout: t(270) = 3.21, p = 0.004). Looking more specifically at early scores by 370 type of opponent faced, we confirm the result from the first experiment that it is easier to 371 transfer learning to the more dissimilar game (Shootout) when facing a level 1 opponent. 372 Indeed, while the early scores of FWG for level-1 and level-2 facing players are not 373

significantly different from each other, the score of the players facing the level-1 opponent is indeed almost 0.2 point per round higher than that of players facing level-2 opponents, and the difference is statistically significant (t(144) = 2.45, p = 0.01). These early scores have also been adjusted to account for the fact that the shootout game has higher average scores when playing randomly, and therefore this difference is really due to better learning transfer and not due to chance.

Computational modelling

To gain more insight into how participants played the games against the computer opponents, we compared multiple models of strategies the players may have been using to learn how to beat the opponent. As a base model, we assume play is random, and each potential action is chosen with equal probability. Note that this corresponds to the Nash equilibrium strategy. In this section, we will go through the various models we have used and explain how they update what they learn about the game or the opponent

387 Reinforcement Learning

380

398

We include for comparison purposes a simple model-free reinforcement learning
algorithm, that reinforces actions that have led to positive rewards, and conversely lowers
the likelihood of choosing actions that led to a negative reward, irrespective of any state. We
will use a simple temporal difference learning update rule:

$$V_{t+1}(a) = V_t(a) + \alpha * (R_t - V_t(a))$$

Where $V_t(a)$ is the value associated with action a at time t, α is the learning rate and R_t the reward at time t. Actions are chosen based on action values using a softmax choice rule.

We extend this very simple model by adding a state space that consists of last round human and agent play. This is akin to using a Q-learning algorithm (Watkins & Dayan, 1992). The update rule becomes:

$$Q^{new}(s_t, a_t) = Q(s_t, a_t) + \alpha * (R_t + \gamma * \max_{a} Q(s_{t+1}, a) - Q(s_t, a_t))$$

Where $Q(s_t, a_t)$ is the value of taking action a when in state s at time t, γ is the

discount rate applied to future rewards. For instance, Q(RS, P) denotes the value of taking action "Paper" this round if the player's last action was "Rock" and the opponent played "Scissors". This is a much richer model allowing the players to compute the values of actions conditional on past play.

In experiment 2, we allow this richer model to have a memory of the interaction. In 403 effect, we have a Q-learning model with a state space consisting of last round play, but in 404 one instance, we fit a model (QLS) in which, when encountering an opponent, learning starts 405 anew with no prior knowledge from previous encounters with the opponent used. In another 406 instance, we fit a model in which what was learned about an opponent in the first interaction 407 is transferred to the first round of the second interaction, so there is a within-game transfer of 408 Q-values allowed (QLS-within). We fit both models to all participant's data in the second 409 experiment where both opponents are faced. 410

EWA Models. Next, we use a self-tuning Experience Weighted attraction model 411 (Ho, Camerer, & Chong, 2004). EWA models particularity is that thet nest two seemingly 412 different approaches, namely reinforcement learning and belief learning. Belief based models 413 are based on the assumption that players keep track of the frequency of past plays and best respond to that. In contrast, reinforcement learning does not take into account beliefs about 415 other players, but is such that an action followed by a positive reward is more likely to be 416 repeated than an action followed by a negative reward. The self-tuning EWA model has 417 been shown to perform better than both these nested models in multiple repeated games and 418 has the advantage of having only one free parameter, the inverse temperature in the softmax 419 choice function. 420

Let's define some notation in order to write the update rule of the self-tuning EWA model. For player i, there are m_i strategies, denoted s_i^j (i.e player i's strategy number j).

Strategies actually played by i in period t, are denoted $s_i(t)$, while the opponent's strategy at time t is denoted $s_{-i}(t)$. After playing s_i^j at time t, player i payoff is denoted $\pi_i(s_i^j, s_{-i}(t))$,

and the actual payoff the player received is $\pi_i(t)$.

429

The EWA model is based on updating "Attractions" for each action over time. For instance, the attraction of strategy j to player i at time t is written $A_i^j(t)$. Future action choice probabilities are based on these attractions using the softmax playing rule:

$$P_i^j(t+1) = \frac{e^{\lambda . A_i^j(t)}}{\sum_{k=1}^{m_i} e^{\lambda . A_i^k(t)}}$$

The attractions are updated over every time step t using the following update rule:

$$A_i^j(t) = \frac{\phi.N(t-1).A_i^j(t-1) + [\delta + (1-\delta).I(s_i^j, s_i(t))].\pi_i(s_i^j, s_{-i}(t))}{\phi.N(t-1) + 1}$$

Here, I(x,y) is the indicator function equal to 1 if x = y and 0 otherwise. A simple 430 way to think about this update rule is that attractions are multipled by a parameter that 431 represents experince (N(t-1)) which is itself decaying by a wight ϕ . The result is added to 432 either the payoff received (when the indicator function is 0), or to δ times the foregone payoff 433 (when indicator function is 1). We can see that setting $\delta = 0$ leads to reinforcement of past 434 actions, while positive and high delta parameters make the update rule take into account 435 foregone payoffs, which is similar to weighted fictitous play (Cheung & Friedman, 1994). 436 While the assumption in expanding the update rule above is that ϕ and δ are free 437 parameters (Camerer, Ho, & Others, 1997), the self-tuning aspect of the model comes from 438 the fact that these are now self-tuned using the formulas expanded in (Ho et al., 2004). 439 **ToM models.** In this set of models, we assume that participants have a belief that the opponent is a level-k agent, with uniform probability of the level k, and use evidence of past play to update their beliefs in a Bayesian way about the true value of k. We use values of k in 0,1,2. We distinguish between multiple ToM models based on their ability to keep 443 what was learned about the opponent in memory and hence facilitate transfer. In a

No-Between-Transfer (NBT) model, players have no memory of what was learned about the opponent and start every new game assuming each level-k has equal probability. In the context of Experiment 2 where players face both opponents, this model assumes that participants transfer learning within the same game, from the first to the second interaction with the opponent, but are not able to transfer that learning to new games (So within but no between trasnfer)

Conversely, In a Between-Transfer model (BT), players are assumed to keep in memory
what was learned about the type of opponent faced (vector of probabilities of level-k) and
use that at the beginning of each new game. In the context of experiment 2, we still assume
that if between transfer is present, then within game transfer is also present (from first to
second interaction).

We fit the above two models to experiment 1 data. In experiment two, on top of these
two models, we fit two other models: One in which we assume that players don't distinguish
between the two opponents faced, so the opponent model vector is never updated (Naive).
And finally, we also fit a model in which all stages of the game and all new games start with
a fresh uniform probability of level-k opponent (NT), so no within or between opponent
model learning transfer.

In summary, we fit two ToM models for experiment 1-play (NBT and BT), and 4 ToM models for experiment 2 (NBT, BT, NT and Naive). In both experiments, all models were fit to each participant data, with optimal parameters being estimated using maximum likelihood. Using information criteria based Bayesian model comparison (BIC), the best fitting model for each participant was chosen and we compared the number of participants whose behavior was best explained by each model.

Experiment 1 modelling:

Figure 7 shows the results for experiment 1: we can see that while some participant's learning behavior was either random or explained by some of the base models, a significant number of participants in experiment one had learning most consistent with Q-learning conditional on last round play.

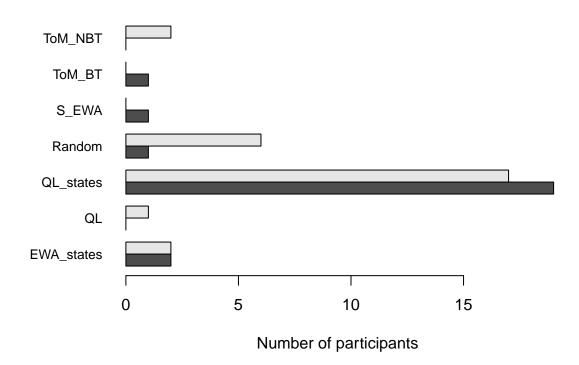

Figure 7. Histogram of best fitting computational models by condition for experiment 1

Next we compared the performance of players whose actions are best fit by each of our hypothesized models. Figure 8 shows the average cumulative performance of players across games, for participants grouped by which model best fits their behavior in experiment 1. We can see that participants whose actions are most consistent with learning a ToM opponent model in a Bayesian way had the best overall performance (witout transfer), followed by Q-learning conditional on last round play. EWA, QL and random players had,

understandably the lowest performance.

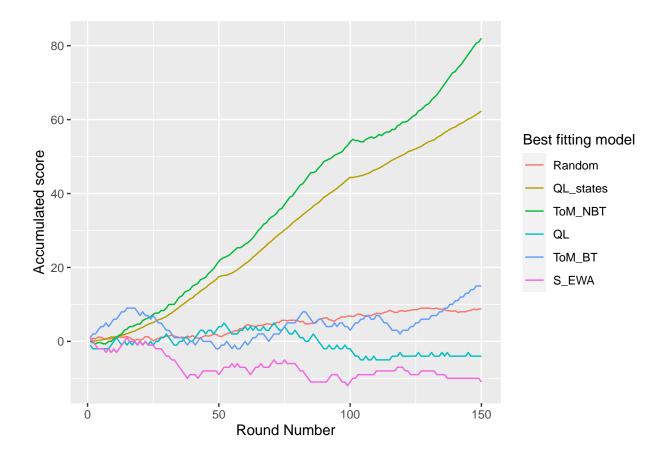

Figure 8. Average cumulative scores of participants in experiment 1 by best fitting model

Experiment 2

481

482

483

484

In experiment 2, we can see from Figure 9 that Q-learning with the aforementioned state-space was again more successful than the bayesian models in fitting player's action choices. In experiment 2 when participants faced both level-1 and level-2 agents sequentially, the bayesian models (with or without transfer) did not fit players observed data as well.

Plotting cumulative scores by best model for experiment 2, we see very similar results looking at Figure 10, in that participants whose behavior was best fit by a ToM model of learning the oppponent strategy had the highest cumulative performance. Out of these ToM models, the one in which there is within-game but no between-game transfer (NBT) had the

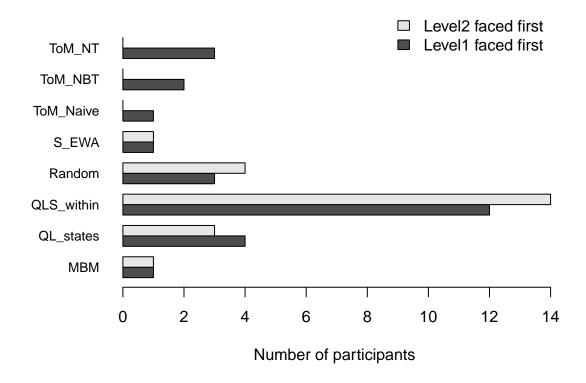

Figure 9. Histogram of best fitting computational models by condition for experiment 2

best cumulative performance, folowed by a model in which both within and between trasnfer of opponent models is allowed (BT). The next best model from a performance perspective was a Q-learning model with states and within game transfer, followed by ToM models where either players started learning from scratch at each stage of each game (NT) and the model in which they didn't distinguish between opponents (Naive). As expected, random play as well as self-tuning EWA were at the bottom of cumulative performance.

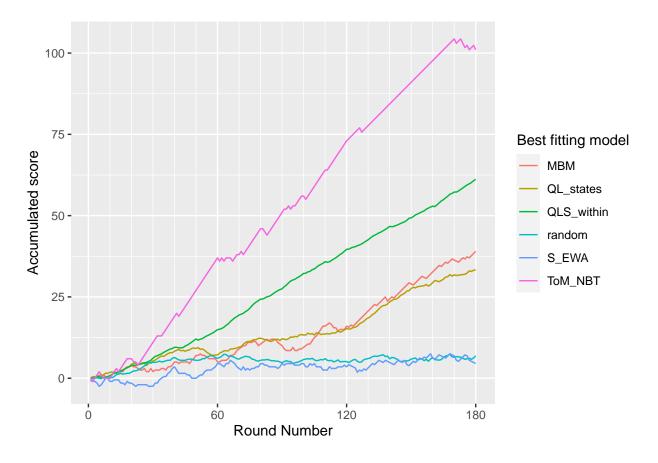

Figure 10. Average cumulative scores of participants in experiment 2 by best fitting model

495 Discussion

In this study, we investigated human learning transfer across games by making human participants play against computer agents with rule-based level-k strategies. We were interested in uncovering evidence for transfer and exploring whether it is modulated by the degree of similarity between games and the sophistication of the agent.

The results of our first online experiment show that the majority of participants learn to adapt to the opponent strategy over multiple interactions and generalise this learning to the similar game. We found that using results on very early rounds is a better proxy for measuring transfer as it is not tainted by any within game learning. Using this approach, we showed that transfer to the more dissimilar game was modulated by the degree of sophistication of the agent, with evidence for transfer when players face the less

sophisticated agent but not the more sophisticated one.

In the second online experiment, the paradigm was better suited to explore our main 507 research question, related to learning transfer rather than within-game learning. Indeed, 508 when facing two opponents sequentially, there are many more opportunities to test transfer 509 than before. Indeed, there are 2 opportunities to transfer knowledge within each game, and a 510 total of three games, which means 6 opportunities to test transfer. When we made players 511 face only one type of opponent each, we only had two possible learning transfers to test. In 512 that regard, the results on learning transfer confirmed prior findings from the first 513 experiment. While there was no evidence of learning transfer across interactions within the 514 same game (likely due to the lower number of rounds per interaction and the higher 515 cognitive load of facing two opponents rather than one), we found evidence for learning 516 transfer across games as early round scores analysis confirmed. We also found that learning 517 transfer is modulated by the type of opponent faced. When the players faced the level-1 518 opponent, they were able to transfer learning. However, when they faced the level-2 519 opponent, there was weaker evidence for transfer. The lack of transfer when facing the more sophisticated opponent might be due to the difficulty of learning that opponent strategy to start with. A player cannot transfer what they have not learnt and as such, since it might be 522 harder to learn the strategy of the level-2 opponent, this in turn might translate into weaker evidence for transfer.

Coming back to evidence for learning transfer, we observed evidence that participants start off new games with prior knowledge as their scores are much higher than chance, confirmed both by early stage analysis as well as rounds 2-6 scores analysis. The question we ask ourselves therefore is: What exactly did the players learn in RPS that allowed them to beat the opponent in FWG and Shootout? what did the players learn exactly about the opponent strategy and what form did this learning take?

We will proceed by considering multiple potential answers to this question. First,

531

maybe players simply learn spatial heuristics that allow them to perform better than chance.

An example is a spatial heuristic that consists of choosing "weapons" in a particular order

(for instance left to right). This was one of the weaknesses in the design of experiment one,

as it was indeed possible using very simple spatial sequences to beat the opponent on most

rounds. We took this into account in designing experiment two by randomly shuffling the

spatial order of action choices in each round. Still, the learning and conclusions were similar,

so this could not explain both learning and transfer in experiments one and two.

A second possible hypothesis for learning the opponent's strategy is the use of simple 539 rules based on last round play (for instance, I play scissors whenver opponent played rock in last round, or whenever the last round play was rock/scissors, I should play paper in this round, etc...). Our Q-learning with states as prior-round play model is a good proxy for this 542 type of strategies. While this approach certainly seemed to be the best fit for some player's 543 behavior, it is unsatisfactory in explaining some of the learning transfer evidence we showed. 544 Indeed, learning the best action in a particular state cannot easily transfer to a new game 545 since the state space is different and there is no simgle mapping between the state spaces of 546 the initial and latter games. These rules would thereofre need to be learned anew in the 547 latter game which is inconsistent with above chance performance in very early rounds. 548

Likewise, assuming that players learn a complete model of the environment (for 540 instance the transition probabilities from last round play to new play) might explain learning 550 within games but is equally unable to account for early games transfer of learning as such 551 models, besides being cognitively very expensive to learn, would require many rounds of practice. Another issue with these hypotheses is that they are not consistent with significant score differences between those facing level-2 and level-1 opponents. After all, if players were 554 using some type of associative learning or spatial heuristics, then their scores should not 555 depend on the degree of strategic sophistication of the opponent since their approaches would 556 render this variable irrelevant. The fact that the degree of sophistication of the opponent 557

matters points to the importance of opponent modelling to successful transfer of learning.

We are left with two possible explanations: First, it is possible that the players have uncovered a heuristic that allows them to beat the opponent without explicitly modelling their strategy, and is robust to transfer. Indeed, because of the cyclicality in action choices (e.g: Rock beats Scissors beats Paper beats Rock), it is possible to beat level-2 opponents most of the time by following a simple rule: Play in the next round whatever the opponent played in the last round. This is a rule that wins and is also robust to transfer as it does not depend on action labels and even works in the dissimilar game.

The second explanation of learning transfer is that it is driven by a group of 566 participants that are able to build a mental representation of what the strategy of the 567 opponent is. A successful mental representation would take the perspective of the opponent 568 or endow it with intentionality in order to detect its strategy when the opponent is playing 569 based on a level-k reasoning model. For instance, the player may think "My opponent is 570 always trying to be one step ahead of me, therefore, I will be one step ahead of where it 571 thinks I will be". This mental representation would facilitate the use of theory of mind 572 abilities and thus enable the players to learn opponent strategies when they are based on 573 human-like reasoning models such as level-k or cognitive hierarchy. This type of learning 574 would be deemed "explicit" in the psychology literature as a process through which knowledge consists of cognitive representations of concepts and rules, as well as the relationship between them. It involves the evaluation of explicit hypotheses and results in better problem-solving skills (Mandler, 2004). Since it is less context dependent, this type of learning is generalizable to new situations, akin to the more general framework of rule-based 579 learning explored by Stahl (2000, 2003). 580

Our second experimental design allows us to test whether the first explanation holds.

Since there is a simple transferable heuristic that works against level-2 players, and since as
far as we know, there are no similar ones against level-1 players, if indeed participants were

using this, they would perform better and transfer learning more easily when facing level-2 opponents. Because level-2 opponents use a higher level of strategic reasoning, they should in fact be harder to play against and in the absence of such a heuristic, performance and learning transfer should be worse.

Our results show that in fact, it was harder to transfer learning when facing level-2
opponents, both comparing first intractions across games and using early rounds analysis.

Based on our assumptions, we conclude that the most likely explanation is that participants
who are able to beat the opponent and transfer learning are likely to be explicitly modelling
the opponent strategy using level-k reasoning, compared to using simple learning rules they
uncovered during the ourse of learning.

594 Conclusion

Our online experiments confirm behavioural game theory results, stating that human 595 players can deviate from Nash equilibrium play and learn to adapt to the opponent strategy 596 and exploit it when the opponent itself is deviating from Nash equilibrium. Moreover, we 597 showed that participants do transfer their learning to new games with varying degrees of 598 similarity. The most likely explanation as we saw is that players build a mental 599 representation of their opponent strategy, rather than rely on associative learning or 600 action-based heuristics. The transfer is also moderated by the level of sophistication of the 601 opponent, with participants showing more success in learning and transferring against 602 opponents adopting a less sophisticated strategy. 603

Having said that, there remains a high degree of heterogeneity between players. There
is a high positive association between players who learn to beat the sophisticated and less
sophisticated opponents, indicating that some players are more able to detect the patterns in
opponent play and learn how to exploit them. Moreover, the computational modelling shows
that a significant number of players are still using random strategies in the games. Whether
this ability depends on engagement with the experiment or on other characteristics of the
learner is an open question that more research in the area would hope to answer.
